Chapter 1

Overview of MethComp

The purpose of the **MethComp** package is to provide computational tools to manipulate, display and analyze data from method comparison studies. A method comparison study is a study where two methods of quantitative measurement are compared by measuring the same set of items with both methods.

There may be more than two methods, and there may be replicate measurements on each item by each method.

1.1 Data structures

In general we are concerned with measurements by different methods, on different items (persons, samples), possibly replicated.

Often such data are represented by a row of measurements for each item, with possible replicates listed either below or beside each other. This implicitly assumes that some replicate measurements belong together, which is not necessarily the case in all situations.

All functions in **MethComp** assume data to be represented in the “long” form, with one measurement on each row, and columns to indicate method, item and replicate. Specifically, we assume the following columns are available in a data frame:

- **meth** The measurement method. Numeric or factor.
- **item** Identification of item (person, sample). Numeric or factor.
- **repl** Replicate number. Numeric or factor.
- **y** The measurement by method **meth** on item **item**, replicate number **repl**.

There is a class, “**Meth**” for this kind of data frame. It is a data frame with the factors **meth**, **item** and **repl** representing the classification, and the numerical variable **y** representing the measurements.

A dataframe with method comparison data in the *long* format is converted to a **Meth** object by using the **Meth** function on it:

```
> data( ox )  
> str( ox )
```

```
'data.frame':      354 obs. of  4 variables:
 $ meth: Factor w/ 2 levels "CO","pulse": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: num  1 1 1 2 2 2 3 3 3 4 ...
 $ repl: num  1 2 3 1 2 3 1 2 3 1 ...
 $ y : num  78 76.4 77.2 68.7 67.6 68.3 82.9 80.1 80.7 62.3 ...
```

```
> ox <- Meth( ox )
```

The following variables from the dataframe
"ox" are used as the Meth variables:

```
meth: meth
item: item
repl: repl
y: y
```

```
      #Replicates
Method  1  2  3 #Items #Obs: 354 Values:  min med max
CO      1  4 56    61    177      22.2 78.6 93.5
pulse   1  4 56    61    177      24.0 75.0 94.0
```

```
> summary( ox )
```

```
      #Replicates
Method  1  2  3 #Items #Obs: 354 Values:  min med max
CO      1  4 56    61    177      22.2 78.6 93.5
pulse   1  4 56    61    177      24.0 75.0 94.0
```

If variables `meth`, `item`, `repl` and `y` are not available in the data frame we may create them on the fly or give the variable positions as arguments to the `Meth` function:

```
> data( fat )
> str( fat )
```

```
'data.frame':      258 obs. of  5 variables:
 $ Id : num  1 1 1 3 3 3 5 5 5 11 ...
 $ Obs: Factor w/ 2 levels "KL","SL": 1 1 1 1 1 1 1 1 1 1 ...
 $ Rep: num  1 2 3 1 2 3 1 2 3 1 ...
 $ Sub: num  1.6 1.7 1.7 2.8 2.9 2.8 2.7 2.8 2.9 3.9 ...
 $ Vic: num  4.5 4.4 4.7 6.4 6.2 6.5 3.6 3.9 4 4.3 ...
```

```
> sc <- Meth( fat, 2, 1, 3, 4 )
```

The following variables from the dataframe
"fat" are used as the Meth variables:

```
meth: Obs
item: Id
repl: Rep
y: Sub
```

```
      #Replicates
Method  3 #Items #Obs: 258 Values:  min med max
KL      43    43    129      0.39 1.7 4.2
SL      43    43    129      0.51 1.7 4.1
```

```
> str( sc )
```

```
Classes 'Meth' and 'data.frame':      258 obs. of  5 variables:
 $ meth: Factor w/ 2 levels "KL","SL": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: Factor w/ 43 levels "1","2","3","4",...: 1 1 1 3 3 3 5 5 5 11 ...
 $ repl: Factor w/ 3 levels "1","2","3": 1 2 3 1 2 3 1 2 3 1 ...
 $ y : num  1.6 1.7 1.7 2.8 2.9 2.8 2.7 2.8 2.9 3.9 ...
 $ Vic : num  4.5 4.4 4.7 6.4 6.2 6.5 3.6 3.9 4 4.3 ...
```

```
> summary( sc )
```

```
      #Replicates
Method      3 #Items #Obs: 258 Values:  min med max
  KL         43    43    129      0.39 1.7 4.2
  SL         43    43    129      0.51 1.7 4.1
```

We may even give some of them as names of the columns in the dataframe:

```
> vi <- Meth( fat, 2,1,"Rep","Vic" )
```

The following variables from the dataframe

"fat" are used as the Meth variables:

```
meth: Obs
item: Id
repl: Rep
  y: Vic
      #Replicates
Method      3 #Items #Obs: 258 Values:  min med max
  KL         43    43    129      2.0 3.9 6.5
  SL         43    43    129      2.3 4.1 6.7
```

However, more complicated operations on the dataframe is best done on the fly using the `with` function (from the `base` package):

```
> data( hba1c )
```

```
> str( hba1c )
```

```
'data.frame':      835 obs. of  6 variables:
 $ dev   : Factor w/ 3 levels "BR.V2","BR.VC",...: 2 2 2 2 2 2 2 2 1 1 ...
 $ type  : Factor w/ 2 levels "Cap","Ven": 2 2 2 2 1 1 1 1 2 2 ...
 $ item  : num  12 12 12 12 12 12 12 12 12 12 ...
 $ d.samp: num  1 1 1 1 1 1 1 1 1 1 ...
 $ d.ana : num  2 3 4 5 2 3 4 5 2 3 ...
 $ y     : num  8.7 8.7 8.7 8.7 9.2 9 8.8 8.7 9.4 9.3 ...
```

```
> hb1 <- with( hba1c,
+             Meth( meth = interaction(dev,type),
+                 item = item,
+                 repl = d.ana-d.samp,
+                 y = y, print=TRUE ) )
```

```
      #Replicates
Method      3      4 #Items #Obs: 835 Values:  min med  max
BR.V2.Cap    0    38    38    152      5.3 8.0 12.6
BR.VC.Cap   19    19    38    133      5.3 8.2 12.1
Tosoh.Cap    0    38    38    152      5.0 7.8 11.8
BR.V2.Ven   19    19    38    133      5.5 8.1 12.0
BR.VC.Ven   19    19    38    133      5.3 8.0 11.6
Tosoh.Ven   20    18    38    132      5.3 8.0 12.1
```

```
> str( hb1 )
```

```
Classes 'Meth' and 'data.frame':      835 obs. of  4 variables:
 $ meth: Factor w/ 6 levels "BR.V2.Cap","BR.VC.Cap",...: 5 5 5 5 2 2 2 2 4 4 ...
 $ item: Factor w/ 38 levels "1","2","3","4",...: 12 12 12 12 12 12 12 12 12 12 ...
 $ repl: Factor w/ 5 levels "0","1","2","3",...: 2 3 4 5 2 3 4 5 2 3 ...
 $ y   : num  8.7 8.7 8.7 8.7 9.2 9 8.8 8.7 9.4 9.3 ...
```

Objects of class `Meth` (which inherits from `data.frame`) has methods such as `summary`, `plot`, `subset` and `transform`. The functions mostly do not require the data to be in `Meth` format — if a dataframe with the right columns is supplied, it is normally converted internally to `Meth` format.

1.1.1 Wide format data

Sometimes data frames comes in the wide format, that is with measurements by different methods in different columns. In this case a **Meth** object is formed by giving the variables containing measurements by different methods as a vector argument to `y`, either as numbers of columns or names of columns:

```
> data( rainman )
> str( rainman )

'data.frame':      30 obs. of  6 variables:
 $ SAND: int  120 48 88 32 24 100 52 80 72 96 ...
 $ ME  : int  175 50 150 45 25 125 70 145 85 110 ...
 $ TM  : int  120 50 75 22 22 80 50 75 90 110 ...
 $ AJ  : int  105 45 75 28 25 91 48 68 55 84 ...
 $ BM  : int  100 50 60 30 20 80 45 55 60 65 ...
 $ LO  : int  100 70 80 30 20 70 50 60 60 65 ...

> RM <- Meth( rainman, item=1, y=2:6 )
```

The following variables from the dataframe "rainman" are used as the Meth variables:

```
item: SAND
y: ME TM AJ BM LO
#Replicates
```

Method	3	#Items	#Obs:	150	Values:	min	med	max
AJ	10	10	30			18	57	120
BM	10	10	30			15	62	120
LO	10	10	30			20	55	100
ME	10	10	30			24	90	200
TM	10	10	30			20	75	120

```
> head( RM )
```

	meth	item	repl	y
1	ME	120	1	175
2	ME	48	1	50
3	ME	88	1	150
4	ME	32	1	45
5	ME	24	1	25
6	ME	100	1	125

1.2 Function overview

The following is a brief overview of the functions in the **MethComp** package. The full documentation is in the help pages for the functions, and an illustration of the way they work can be obtained by referring to the examples in the help pages. The help page for `plot.meth` is brought up by:

```
> ?plot.Meth
```

The example code from the manual page can be run directly by:

```
> example( plot.Meth )
```

1.2.1 Graphical functions

The graphical functions generally have a lot of arguments that can be used to fine-tune the looks of the plots. Refer to the help page for each to see them all.

BA.plot Makes a Bland-Altman plot of two methods from a data frame with method comparison data, and computes limits of agreement. The plotting is really done by a call to the function **BlandAltman**. The default is to plot the two first methods against each other.

BlandAltman draws a Bland-Altman plot and computes limits of agreement.

bothlines Adds regression lines of y on x and vice versa to a scatter plot. Optionally, the Deming regression line can be added too.

plot.Meth Plots all methods against each other in a square matrix, both as a scatter plot (below diagonal) and as a Bland-Altman plot (above diagonal).

plot.MethComp plots the estimated conversion between methods with a ± 2 sd interval, corresponding to approx. 95% prediction interval. Recognizes transformations applied to data.

1.2.2 Data manipulating functions

make.repl Generates (or replaces) a **repl** column in a **Meth** object.

perm.repl Randomly permutes replicates within (**method,item**) and assigns new replicate numbers.

to.wide Transforms a data frame in the long form to the wide form where separate columns for each method are generated, with one row per (**item, repl**).

to.long Reverses the result of **to.wide**. The function can also generate a long form dataset from a dataset with different methods beside each other.

summary.Meth Tabulates items by method and no. replicates for a **Meth** object.

Meth.sim Simulates a dataset from a method comparison experiment for given parameters for bias, exchangeability and variance component sizes.

1.2.3 Analysis functions

DA.reg Regresses the differences between methods on the averages and derives approximate linear conversion equations, based on **[?]**.

Deming Performs Deming regression, i.e. regression with errors in both variables.

BA.est Estimates in the variance components models underlying the concept of limits of agreement, and returns the bias and the variance components. The model used assumes constant bias between methods.

AltReg Estimates via alternating regressions in the general model. Returns estimates of mean conversion parameters and variance components.

MCmcmc Estimates via BUGS in the general model with non-constant bias (and in the future) possibly non-constant standard deviations of the variance components. Produces a **MCmcmc** object, which is an **mcmc.list** object with some extra attributes. **mcmc.list** objects are handled by the **coda** package, so this is required when calling **MCmcmc**.

1.2.4 Reporting functions

Some of these functions take an **MCmcmc** object as input, others will postprocess the output of **DA.reg**, **BA.est** or **AltReg**.

The functions **DA.reg**, **BA.est**, **AltReg** return objects that have class **MethComp**, whereas the result of **MCmcmc** can be converted to an object of this type by the **MethComp** function. The reason for this is that the results of the **MCmcmc** function is output from an MCMC-simulation which we may want to monitor by special functions. The **MethComp** function only extracts the central summaries from the **MCmcmc** object assuming the chains have reached convergence.

print.MethComp Prints a table of conversion equation between methods analyzed, with prediction standard deviations.

print.MCmcmc Prints a table of conversion equation between methods analyzed, with prediction standard deviations, but also gives summaries of the posteriors for the parameters that constitute the conversion algorithms.

plot.MethComp, **plot.MCmcmc** Plots the conversion lines between methods with prediction limits.

post.MCmcmc Plots smoothed posterior densities for the estimates. Primarily of interest for the variance components, but it has arguments to produce the posterior of the intercepts and the slopes of the conversion lines between methods too.

check.MCmcmc Makes diagnostic plots of the traces of the chains included in the **MCmcmc** object.

Chapter 2

Worked examples

2.1 Fat measurements: Exchangeable replicates

The `fat` data from the `MethComp` package contains measurements of subcutaneous and visceral fat on 43 persons, by two observers, KL and SL. Each measurement is replicated 3 times.

First we examine the names in the dataframe, and then use `Meth` to convert it to a form that comply with that required by the functions in the `MethComp` package for analyzing visceral fat — we convert it to a `Meth` object:

```
> data(fat)
> str(fat)

'data.frame':      258 obs. of  5 variables:
 $ Id : num  1 1 1 3 3 3 5 5 5 11 ...
 $ Obs: Factor w/ 2 levels "KL","SL": 1 1 1 1 1 1 1 1 1 1 ...
 $ Rep: num  1 2 3 1 2 3 1 2 3 1 ...
 $ Sub: num  1.6 1.7 1.7 2.8 2.9 2.8 2.7 2.8 2.9 3.9 ...
 $ Vic: num  4.5 4.4 4.7 6.4 6.2 6.5 3.6 3.9 4 4.3 ...
```

```
> vis <- Meth( fat, 2,1,3,5 )
```

The following variables from the dataframe
"fat" are used as the Meth variables:

meth: Obs

item: Id

repl: Rep

y: Vic

#Replicates

Method	3	#Items	#Obs:	258	Values:	min	med	max
KL	43	43	129		2.0	3.9	6.5	
SL	43	43	129		2.3	4.1	6.7	

```
> str(vis)
```

```
Classes 'Meth' and 'data.frame':      258 obs. of  5 variables:
 $ meth: Factor w/ 2 levels "KL","SL": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: Factor w/ 43 levels "1","2","3","4",...: 1 1 1 3 3 3 5 5 5 11 ...
 $ repl: Factor w/ 3 levels "1","2","3": 1 2 3 1 2 3 1 2 3 1 ...
 $ y : num  4.5 4.4 4.7 6.4 6.2 6.5 3.6 3.9 4 4.3 ...
 $ Sub: num  1.6 1.7 1.7 2.8 2.9 2.8 2.7 2.8 2.9 3.9 ...
```

```
> summary(vis)
```

Figure 2.1: *Two observers measuring visceral fat.*

	#Replicates							
Method	3	#Items	#Obs:	258	Values:	min	med	max
KL	43	43		129		2.0	3.9	6.5
SL	43	43		129		2.3	4.1	6.7

The two methods plotted against each other requires that we use the replicate number for pairing the measurements; so we just keep the ordering among the replicates when using `to.wide`:

```
> pw <- to.wide( vis )
```

Note:

Replicate measurements are taken as separate items!

```
> par( mar=c(3,3,1,1) )
> with(pw, plot( SL ~ KL, pch=16, xlim=range(vis$y), ylim=range(vis$y) ) )
> abline( 0,1 )
```

Since replicates are exchangeable *within* (method, item) we should get the same sort of overview of the data after a random permutation of the replicates. Plotting the data using the original replicate numbers for pairing and then a random permutation is shown in figure 2.2:

```
> plot( vis )
```

Figure 2.2: Plot of two methods of measuring visceral fat, using different pairings of the replicates; the left panel is using the pairing in the original coding, the right panel is with a random permutation of replicates.

Note:

Replicate measurements are taken as separate items!

```
> plot( perm.repl( vis ) )
```

Note:

Replicate measurements are taken as separate items!

These two plots are shown in figure 2.2 where it is pretty clear that the random permutation of replicates has little effect.

BA.plot produces a Bland-Altman plot and computes the limits of agreement using the pairing of replicates across methods based on the numbering of replicates. However we do not want the replicates to be connected, so we must specify this explicitly:

```
> par( mar=c(3,3,3,3), mgp=c(3,1,0)/1.6 )
> BA.plot( vis, conn.repl=FALSE )
```

Limits of agreement:

SL - KL	2.5% limit	97.5% limit	SD(diff)
0.1550388	-0.5612718	0.8713493	0.3581553

We see that using this approximation we get limits of agreement for KL–SL of $(-0.86, 0.55)$.

Moreover, there seems to be no indication that the difference between observers or the variance varies with the level of measurement. This can be a bit more formally tested using the DA.reg function (again using the existing pairing of replicates):

```
> DA.reg( vis )
```

Figure 2.3: *Bland-Altman plot of two observers measuring visceral fat.*

Conversion between methods:

To: From:		alpha	beta	sd.pred	beta=1	sd. A=4	slope(sd)	sd.=K
KL	KL	0.000	1.000	NA	NA	NA	NA	NA
	SL	-0.340	1.044	0.365	0.158	0.366	-0.024	0.275
SL	KL	0.326	0.957	0.349	0.158	0.366	-0.024	0.275
	SL	0.000	1.000	NA	NA	NA	NA	NA

From the last two columns (p-values for tests of constant difference and constant sd.) it is clear that there are no obvious violations of the assumptions about constant difference or about constant variation across the range of measurements.

Setting up a proper variance component model we get only slightly different limits of agreement (note that we must specify the replicates to be exchangeable):

```
> ( vis.est <- BA.est( vis, linked=FALSE ) )
```

Conversion between methods:

To: From:		alpha	beta	sd	LoA: lower	upper
KL	KL	0.000	1.000	0.273	-0.545	0.545
	SL	-0.155	1.000	0.364	-0.883	0.573
SL	KL	0.155	1.000	0.364	-0.573	0.883
	SL	0.000	1.000	0.245	-0.490	0.490

Variance components (sd):

IxR	MxI	res
-----	-----	-----

Figure 2.4: *Bland-Altman-plot of two methods of measuring visceral fat, using different pairings of the replicates. The blue lines are the LoA based on taking the paired replicates as items, the red lines are based on the estimates from the proper variance component model.*

```
KL  0 0.181 0.193
SL  0 0.181 0.173
```

Moreover we get the coefficient of reproducibility for each of the methods; that is an upper 95% confidence interval for the absolute difference between two measurements by the same method on the same

We can visualize the difference between the *ad-hoc*-computed LoA and the model based ones by plotting them in the same graph:

```
> par( mar=c(3,3,1,3), mgp=c(3,1,0)/1.6 )
> BA.plot( vis, conn.repl=FALSE )

Limits of agreement:
  SL - KL  2.5% limit 97.5% limit   SD(diff)
0.1550388 -0.5612718  0.8713493  0.3581553

> abline( h=vis.est$LoA[1:3], col="red" )
```

As predicted by the theory, the limits based on the *ad-hoc* paired replicates are roughly equal to those derived from the proper variance component model — see figure 2.4.

Figure 2.5: *Bland-Altman-plot of two methods of measuring visceral fat, based on the arbitrary pairing of the replicates (black) and on the mean over replicates (grey).*

In order to illustrate the effect of basing the limits of agreement on the mean over the replicates we use the argument `mean.repl`, and the trick of using `par(new=T)` to over plot:

```
> par( mar=c(3,3,1,3), mgp=c(3,1,0)/1.6 )
> BA.plot(vis,mean.repl=T,limy=c(-1,1),limx=c(2,7),col=gray(0.7),col.lines=gray(0.5), conn.repl=FALSE)
```

Limits of agreement:

SL - KL	2.5% limit	97.5% limit	SD(diff)
0.1550388	-0.4371295	0.7472070	0.2960841

```
> par(new=T)
> BA.plot(vis,mean.repl=F,limy=c(-1,1),limx=c(2,7),cex=0.7,conn.repl=FALSE)
```

Limits of agreement:

SL - KL	2.5% limit	97.5% limit	SD(diff)
0.1550388	-0.5612718	0.8713493	0.3581553

The two superposed Bland-Altman plots are shown in figure ??.

2.2 Cardiac output: Linked replicates?

The dataset is adapted from table 4 in: JM Bland and DG Altman: Measuring agreement in method comparison studies. Statistical Methods in Medical Research,

8:136-160, 1999. Originally supplied to Bland & Altman by Dr LS Bowling, see: Bowling LS, Sageman WS, O'Connor SM, Cole R, Amundson DE. Lack of agreement between measurement of ejection fraction by impedance cardiography versus radionuclide ventriculography. Critical Care Medicine 1993; 21: 1523-27.

It consists of measurements of cardiac output on 12 persons. For each person the cardiac output is measured repeatedly (three to six times) by impedance cardiography (IC) and radionuclide ventriculography (RV).

The dataset is supplied with the MethComp package, and comes with the correct variable names, so it can immediately be transformed into a Meth object:

```
> data( cardiac )
> cardiac <- Meth( cardiac )
```

The following variables from the dataframe "cardiac" are used as the Meth variables:

```
meth: meth
item: item
repl: repl
y: y
```

```
#Replicates
Method 3 4 5 6 #Items #Obs: 120 Values: min med max
IC 1 3 3 5 12 60 2.32 4.610 7.40
RV 1 3 3 5 12 60 2.85 5.105 7.89
```

It is not clear from the description of the dataset whether replicates are linked across methods or not, but a quick check can be made graphically by making a Bland-Altman plot on the data as supplied and on the data where replicates are randomly permuted, and then compare them as in figure 2.2.

```
> par( mfrow=c(1,2), mar=c(3,3,1,3), mgp=c(3,1,0)/1.6 )
> BA.plot( cardiac , limy=c(-3,3) )
```

```
Limits of agreement:
RV - IC 2.5% limit 97.5% limit SD(diff)
0.6021667 -1.3199476 2.5242809 0.9610571
```

```
> BA.plot( perm.repl(cardiac), limy=c(-3,3) )
```

```
Limits of agreement:
RV - IC 2.5% limit 97.5% limit SD(diff)
0.6021667 -1.3471230 2.5514563 0.9746448
```

A slightly more formal handle can be obtained by fitting models assuming constant difference between methods. The models are fitted, one with an item(=person) by replicate effect, and one without:

```
> BA.est( cardiac, linked=TRUE )
```

```
Conversion between methods:
alpha beta sd LoA: lower upper
To: From:
IC IC 0.000 1.000 0.449 -0.898 0.898
RV -0.705 1.000 1.022 -2.748 1.339
RV IC 0.705 1.000 1.022 -1.339 2.748
RV RV 0.000 1.000 0.374 -0.749 0.749
```

```
Variance components (sd):
IxR MxI res
IC 0.193 0.661 0.317
RV 0.193 0.661 0.265
```

Figure 2.6: Bland-Altman plots of the cardiac data. The left panel is the original data using replicate numbers to pair measurements, the right is using a random permutation of replicates for the pairing. Even if replicates are claimed to be linked, the replicates the LoA in the right panel are not substantially wider.

```
> BA.est( cardiac, linked=FALSE )
```

```
Conversion between methods:
      alpha  beta   sd  LoA: lower  upper
To: From:
IC  IC      0.000 1.000 0.525      -1.050  1.050
    RV     -0.702 1.000 1.049      -2.801  1.396
RV  IC      0.702 1.000 1.049      -1.396  2.801
    RV      0.000 1.000 0.463      -0.926  0.926

Variance components (sd):
      IxR  MxI  res
IC      0 0.654 0.371
RV      0 0.654 0.328
```

We see that there is a some variation between replicates, which we would not expect to see if replicates were exchangeable. In the model where we (erroneously) assume replicates to be exchangeable, we see that it is the residual variances that gets inflated. We can check the assumptions about constant bias and constant variance across the range of measurements by fitting a straight line to the differences as function of the averages (using the given linking of replicates). Note that the argument `reg.line=3` gives printed output and graph annotation of the relationship between methods with three digits after the decimal point:

```
> BA.card <- BA.plot( cardiac, limy=c(-2,4), reg.line=3 )
```

```
Limits of agreement:
      RV - IC  2.5% limit 97.5% limit  SD(diff)
0.6021667 -1.3199476  2.5242809  0.9610571
```

RV-IC = 0.422 + 0.036 (RV+IC)/2 (95% p.i.: +/-1.937)
 res.sd = 0.968 se(beta) = 0.103 , P = 0.7300

IC = -0.415 + 0.965 RV (95% p.i.: +/-1.903)
 RV = 0.430 + 1.036 IC (95% p.i.: +/-1.972)

Figure 2.7: *Bland-Altman plot of the cardiac data with a fitted regression line.*

There is a some indication that the variance is not constant, but seen from the figure it does not seem alarming, it presumably hinges on the 6 points to the far left of the plot. An informal test of this can be obtained by using the function `DA.reg`, which regresses the Differences between methods on the Averages, and additionally regresses the

absolute values of the residuals from this analysis on the averages, so as to give an indication as to whether the residual standard deviation depends linearly on the mean:

```
> DA.reg( cardiac )
```

```
Conversion between methods:
      alpha  beta sd.pred  beta=1  sd.|A=4.8  slope(sd)  sd.=K
To: From:
IC  IC      0.000  1.000      NA      NA      NA      NA      NA
    RV     -0.415  0.965  0.951  0.730  0.943  0.168  0.021
RV  IC      0.430  1.036  0.986  0.730  0.943  0.168  0.021
    RV      0.000  1.000      NA      NA      NA      NA      NA
```

If we fit a variance component model using `BA.est` as before, we can explore what effect it has on the repeatability (the prediction of a method from itself) if we include the variation between replicates or not:

```
> BA.est( cardiac, linked=TRUE, IxR.pr=FALSE )
```

```
Conversion between methods:
      alpha  beta      sd  LoA: lower  upper
To: From:
IC  IC      0.000  1.000  0.449      -0.898  0.898
    RV     -0.705  1.000  1.022      -2.748  1.339
RV  IC      0.705  1.000  1.022      -1.339  2.748
    RV      0.000  1.000  0.374      -0.749  0.749
```

```
Variance components (sd):
      IxR  MxI  res
IC 0.193 0.661 0.317
RV 0.193 0.661 0.265
```

```
> BA.est( cardiac, linked=TRUE, IxR.pr=TRUE )
```

```
Conversion between methods:
      alpha  beta      sd  LoA: lower  upper
To: From:
IC  IC      0.000  1.000  0.525      -1.050  1.050
    RV     -0.705  1.000  1.022      -2.748  1.339
RV  IC      0.705  1.000  1.022      -1.339  2.748
    RV      0.000  1.000  0.463      -0.926  0.926
```

```
Variance components (sd):
      IxR  MxI  res
IC 0.193 0.661 0.317
RV 0.193 0.661 0.265
```

The former is for the situation where we consider the variation between replicate measurements as a part of the repeatability conditions (even if the replicates are linked), the latter where we consider the variation between replicates to be irrelevant to the assessment of repeatability. However there is not much indication of linked estimates, since the other two variance components are virtually unchanged between the two analyses, and hence the predictions between methods based on the two approaches will be the same.

2.3 Systolic blood pressure: Linked replicates by two methods

We first load the systolic blood pressure data from the MethComp package.

```
> data( sbp )
> sbp <- Meth( sbp )

The following variables from the dataframe
"sbp" are used as the Meth variables:
meth: meth
item: item
repl: repl
y: y
#Replicates
Method      3 #Items #Obs: 765 Values:  min med max
  J         85     85    255         74 120 228
  R         85     85    255         76 120 226
  S         85     85    255         77 135 228

> str(sbp)

Classes 'Meth' and 'data.frame':      765 obs. of  4 variables:
 $ meth: Factor w/ 3 levels "J","R","S": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: Factor w/ 85 levels "1","2","3","4",...: 1 2 3 4 5 6 7 8 9 10 ...
 $ repl: Factor w/ 3 levels "1","2","3": 1 1 1 1 1 1 1 1 1 1 ...
 $ y   : num  100 108 76 108 124 122 116 114 100 108 ...

> plot( sbp )
```

Note:
Replicate measurements are taken as separate items!

The resulting plot is shown in figure 2.8, clearly shows that the two manual measurements are in much closer agreement than any of them are with the automatic.

`plot.Meth` pairs replicates according to their numbering and treat them as separate items, so the plots fail to take the dependence of observations into account.

We want to restrict our attention to the comparison of the two manual methods, but using the replicate measurements.

In this context it is important that we recognize whether the replicates are linked across the two methods or not. In this case they are, *i.e.* replicates are not exchangeable within methods and items.

```
> par( mar=c(3,3,3,3), mgp=c(3,1,0)/1.6 )
> sbp <- subset( sbp, meth %in% c("J","R") )
> str( sbp )

Classes 'Meth' and 'data.frame':      510 obs. of  4 variables:
 $ meth: Factor w/ 2 levels "J","R": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: Factor w/ 85 levels "1","2","3","4",...: 1 2 3 4 5 6 7 8 9 10 ...
 $ repl: Factor w/ 3 levels "1","2","3": 1 1 1 1 1 1 1 1 1 1 ...
 $ y   : num  100 108 76 108 124 122 116 114 100 108 ...

> BA.plot( sbp )

Limits of agreement:
      R - J  2.5% limit 97.5% limit   SD(diff)
-0.08627451 -4.60761840  4.43506938  2.26067194
```

A slightly more informative plot can be obtained by explicitly regulating the y -dimension of the plot by the argument `ymax=`:

```
> BA.plot( sbp, ymax=15 )
```

```
Limits of agreement:
      R - J  2.5% limit 97.5% limit    SD(diff)
-0.08627451 -4.60761840  4.43506938  2.26067194
```

The resulting plots are shown in figure 2.9.

In order to properly partition the variance and produce limits of agreement or a translation between the two observers, we should fit the relevant variance component model, assuming linked replicates:

$$y_{mir} = \alpha_m + \mu_i + a_{ir} + c_{mi} + e_{mir}, \quad a_{ir} \sim \mathcal{N}(0, \omega^2), \quad c_{mi} \sim \mathcal{N}(0, \tau_m^2), \quad e_{mir} \sim \mathcal{N}(0, \sigma_m^2)$$

Since we only have two methods, we cannot identify separate variance components τ_1 and τ_2 , so we are forced to assume that $\tau_1 = \tau_2$, hence the use of `pdIdent` and not `pdDiag` in the specification of the matrix effects (*i.e.* the method by item interactions). The model above is fitted to the dataset by:

Figure 2.8: Graphical overview of the `sbp` data. The methods *J* and *R* are two human observers, whereas method *S* is an automatic device.

```
> m1 <- lme( y ~ meth + item,
+           random=list( item = pdIdent( ~ meth-1 ),
+                       repl = ~ 1 ),
+           weights = varIdent( form = ~1 | meth ),
+           data = sbp )
> m1
```

Linear mixed-effects model fit by REML

```
Data: sbp
Log-restricted-likelihood: -1163.807
Fixed: y ~ meth + item
```

Figure 2.9: Bland-Altman plot of the sbp data. Replicates are linked between methods, so the single replicates in the data has been used as single measurements when doing the Bland-Altman plot. Measurements from the same person are joined by thin lines. The only difference between the two plots is the scaling of the y-axis.

```

53.82189382 29.59542419 9.52418172 13.22646963 17.52418172 112.63104543
   item72      item73      item74      item75      item76      item77
30.55980296 53.89313629 -19.44019704 70.48856049 75.59542419 13.22646963
   item78      item79      item80      item81      item82      item83
15.29771210 4.55980296 6.26209086 36.78627258 4.78627258 6.92875753
   item84      item85
-2.10686371 12.48856049

Random effects:
Formula: ~meth - 1 | item
Structure: Multiple of an Identity
           methJ      methR
StdDev: 0.2483701 0.2483701

Formula: ~1 | repl %in% item
      (Intercept) Residual
StdDev: 5.932962 1.48587

Variance function:
Structure: Different standard deviations per stratum
Formula: ~1 | meth
Parameter estimates:
           J           R
1.000000 1.122211
Number of Observations: 510
Number of Groups:
      item repl %in% item
      85      255

```

Now, the output from `lme` is pretty difficult to read, but the residual standard deviations are $\sigma_J = 1.485870$ and $\sigma_R = 1.485870 \times 1.122211 = 1.6674599$, whereas $\tau = 0.2483701$ (largely negligible) and $\omega = 5.932962$, by far the largest variance component. Also from the output we get the difference between methods R and J to be -0.08627451 .

An easier way to get the relevant estimates is to use the wrapper `BA.est`, where the only necessary specification is the dataset (assuming that columns `meth`, `item`, `repl` and `y` are present) and whether replicates are linked across methods:

```

> BA.est( sbp, linked=TRUE )

Conversion between methods:
      alpha  beta   sd  LoA: lower  upper
To: From:
J   J      0.000 1.000 2.101      -4.203  4.203
   R      0.086 1.000 2.261      -4.435  4.608
R   J     -0.086 1.000 2.261      -4.608  4.435
   R      0.000 1.000 2.358      -4.716  4.716

Variance components (sd):
      IxR  MxI  res
J 5.933 0.248 1.486
R 5.933 0.248 1.667

```

Which is identical to the quantities we fished out of the `lme` output. Actually `BA.est` fits exactly the model we fitted, and then extracts the quantities that we are interested in.

The limits of agreement between the two manual observers is then for $R-J$ $-0.0863 \pm 1.96 \times \sqrt{2 \times 0.248^2 + 1.486^2 + 1.667^2} = (-4.51, 4.34)$, i.e. on average they agree, but in order to be sure to enclose 95% of all differences we need an interval approximately as 0 ± 4.5 mmHg.

One way of seeing the lack of exchangeability is to make the overview plot using a random permutation of the replicates. If replicates were truly exchangeable within methods the plot would look similar when permuting the replicates — and it does not!

For completeness we reload the data to get observations by all three methods included, and then make overview plots after random permutation of replicates within (method,item):

```
> data(sbp)
> sbp <- Meth( sbp )
```

The following variables from the dataframe "sbp" are used as the Meth variables:

```
meth: meth
item: item
repl: repl
y: y
```

```
#Replicates
Method      3 #Items #Obs: 765 Values:  min med max
      J      85      85      255      74 120 228
      R      85      85      255      76 120 226
      S      85      85      255      77 135 228
```

```
> str(sbp)
```

```
Classes 'Meth' and 'data.frame':    765 obs. of  4 variables:
 $ meth: Factor w/ 3 levels "J","R","S": 1 1 1 1 1 1 1 1 1 1 ...
 $ item: Factor w/ 85 levels "1","2","3","4",...: 1 2 3 4 5 6 7 8 9 10 ...
 $ repl: Factor w/ 3 levels "1","2","3": 1 1 1 1 1 1 1 1 1 1 ...
 $ y    : num  100 108 76 108 124 122 116 114 100 108 ...
```

```
> plot( perm.repl(sbp) )
```

Note:

Replicate measurements are taken as separate items!

The two resulting plots are shown in figure 2.10.

The analysis should be based on a model where a random item by replicate effect is included to accomodate the linking of replicates:

```
> BA.est( sbp, linked=TRUE )
```

```
Conversion between methods:
      alpha      beta      sd  LoA: lower  upper
To: From:
J   J      0.000    1.000    2.305      -4.610    4.610
   R      0.086    1.000    2.272      -4.459    4.631
   S     -15.620    1.000   20.326     -56.272   25.032
R   J     -0.086    1.000    2.272      -4.631    4.459
   R      0.000    1.000    2.187      -4.375    4.375
   S     -15.706    1.000   20.317     -56.339   24.927
S   J      15.620    1.000   20.326     -25.032   56.272
   R      15.706    1.000   20.317     -24.927   56.339
   S      0.000    1.000   12.930     -25.860   25.860
```

```
Variance components (sd):
      IxR      MxI      res
J 5.887  0.338  1.630
R 5.887  0.001  1.547
S 5.887 18.077  9.143
```

The substantial item by replicate interaction (IR) clearly indicates that replicates are linked between methods.

The resulting estimates from this model gives limits of agreement for R–J based on the method by item and the residual variances:

$$-0.0863 \pm 1.96 \times \sqrt{0.3385^2 + 0.0011^2 + 1.6301^2 + 1.5467^2} = -0.0863 \pm 4.4540 = (-4.54, 4.37)$$

which is in agreement with the limits computed based on the simplistic way of taking replicates as items — a procedure which is actually close to correct if replicates are linked.

Alternatively this could be formulated as a 95% prediction interval for R given a measurement by J, y_J , which would be

$$y_R | y_J = y_J - 0.0863 \pm 4.4540 = y_J + (-4.54; 4.37)$$

The above analysis is based on the correct analysis of the entire dataset, including the information from the machine measurement S. If we fit the model on the restricted dataset, we of course get a common method by item interaction term because we then only have two methods:

```
> BA.est( subset( sbp, meth!="S" ), linked=TRUE )
```

```
Conversion between methods:
      alpha  beta   sd  LoA: lower  upper
To: From:
J   J       0.000 1.000 2.101      -4.203  4.203
    R       0.086 1.000 2.261      -4.435  4.608
R   J      -0.086 1.000 2.261      -4.608  4.435
    R       0.000 1.000 2.358      -4.716  4.716
```

```
Variance components (sd):
```

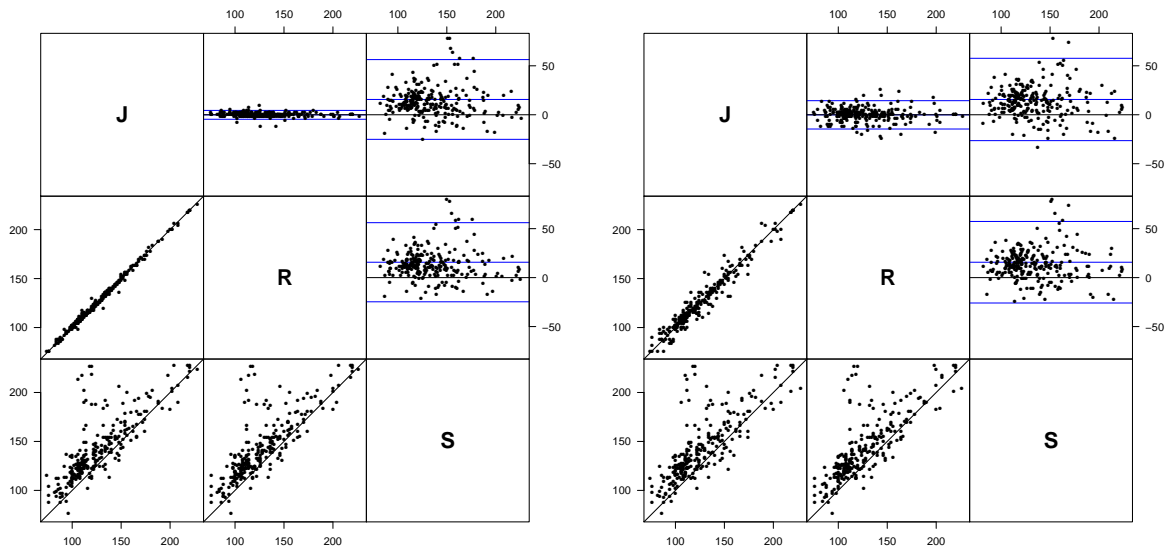

Figure 2.10: Graphical overview of the *sbp* data; the left panel with the original replicate numbers used for matching; the other with replicates permuted randomly within methods.

	IxR	MxI	res
J	5.933	0.248	1.486
R	5.933	0.248	1.667

Based on these estimates we get the limits of agreement for R–J to be:

$$-0.0863 \pm 1.96 \times \sqrt{2 \times 0.2484^2 + 1.4859^2 + 1.6674^2} = 0.0863 \pm 4.4313 = (-4.52, 4.35)$$

i.e. effectively the same as before, based on all three methods. Again these limits are those computed by `BA.est`.
